13. ABSTRACT (Maximum 200 words) Distributed simulation plays an important role for the military modeling and simulation community. Various reasons support the integration of independent simulators into distributed simulation federations. Among these are the increased computational power becoming available, and the possibility of reusing already existing sophisticated software simulations for new purposes, ie a leveraging motivation. The US Department of Defense has devised its own standard for simulation reuse and interoperability, the High Level Architecture (HLA). The purpose of this report is firstly to analyze some of the issues that are related to distributed simulation in general. These issues include, for example, concepts of simulation timing or issues of simulation interoperability. Secondly, a close look has to be taken at the HLA and its implementation, the Run Time Infrastructure RTI, to get a better understanding of the capabilities and the functioning of this tool. One goal of the effort reported on is to evaluate the HLA's particular applicability for the simulation of distributed data fusion and for military development, testing and evaluation (DT&E). Thirdly, a concept is devised for making use of the rather-complex HLA/RTI tool for small-scale university-type distributed simulation research. This is done by implementing an easy-to-use programming environment, based on HLA, and necessary control and support tools. In this report, this is called the "CMIF HLA Environment", as the work was conducted at the State University of New York's "Center for Multisource Information Fusion or CMIF. As the last part of this work, a first proof of concept experiment/demo is done to validate the implemented software. This is realized by constructing a demo application, a distributed simulation experiment with several components that make use of all the features and mechanisms of the CMIF HLA Environment.

Kai Harth

February 1, 2001

A thesis submitted to the
Faculty of the Graduate School of the
State University of New York at Buffalo
in partial fulfillment of the requirements for the
degree of
Master of Science

Department of Mechanical and Aerospace Engineering

Acknowledgements

My pursuing of the degree of Master of Science would have been out of question without the help and support of many generous people. I am deeply grateful. The following list is without order and makes no claim to completeness:

The German Fulbright Commission, for giving me the chance to come to the United States for graduate studies in the first place.

Professor James Llinas, my advisor. Despite his workload, he never failed to support me during eventual technical and motivational difficulties. His funding gave me the chance to extend my stay and even return to Buffalo twice. The CMIF lab became something like a second home.

The Department of Mechanical and Aerospace Engineering and its faculty, for providing an excellent and challenging academic environment.

My committee members, Professor Crassidis and Professor Mook, for taking their time to read through all of this.

My family and friends, for always encouraging and supporting me, and for letting me go at all.

Abstract

Chapter 1

Introduction

1.1 Background

The importance of computers, especially computer simulation, in today's technical world is continuously increasing. It is widely accepted, that the use of computer simulation can save valuable time and costly resources. This is also true for the realm of military applications, where simulations are used over a wide range, from training up to research and development (R&D). Over time, two situations have evolved: Firstly, simulation scenarios tend to become more and more complex. And secondly, a large number of sophisticated and specialized simulators are already available and a reuse of these software programs is desirable. This lead to the field of distributed simulation, where different simulation programs are interconnected and cooperate with each other to form a new simulation application. Although the approach of distributed simulation is promising and offers a solution to both problems –increasing

complexity and the desire for reuse— it also raises a lot of new questions and issues: Interface and communication standards are needed and general aspects of simulation interoperability need to be dealt with.

This work is part of the research efforts of the Center for Multisource Information Fusion, CMIF. The CMIF, which is headed by Professor James Llinas, Ph.D., is a research facility at the State University of New York at Buffalo. Part of the research, which is done, is concerned with distributed data fusion, a field that is closely related to that of distributed simulation.

The data fusion research has lead to a close cooperation between the CMIF and the US military, more specifically, the Air Force Electronic Warfare Flight Test Range Facility at Edwards Air Force Base. There, Test and Evaluation (T&E) experiments are conducted with electronic warfare components, on in-flight platforms as well as in laboratory test-stands. The test ranges —Electronic Combat Range and Nellis Range Complex— are instrumented and populated with high-fidelity, manned or unmanned threat simulators. Additional emitter-only threat simulators are used to provide high signal density, typical of operational electronic warfare environments.

The US military has its own standards for distributed simulation. Two older ones, DIS¹ and ALSP² are being phased out now. Their successor is the High Level Architecture (HLA) which features new and improved capabilities. In this treatise, the HLA will be analyzed and then a concept will be devised how to utilize the HLA in the form of a lab environment for distributed data fusion research at CMIF. Also, the implementation of this concept, the “CMIF HLA Environment”, will be introduced.

¹DIS—Distributed Interactive Simulation

²ALSP—Aggregate Level Simulation Protocol

1.2 Purpose of this work

The initial motivation for this project was to analyze future scenarios for the Edwards AFB Range Testing Facility. The question is: How will distributed simulation contribute to and enhance testing of electronic warfare components? To be able to answer this, it was first necessary to become more familiar with the general aspects of distributed simulation. The High Level Architecture (HLA) then came into focus because it is the mandatory framework for all future military simulations. After a closer look was taken at the HLA and its implementation, the Run Time Infrastructure, it became clear that this was a tool with great capabilities. It would also be desirable to utilize it for the distributed data fusion research done by CMIF in general. Thus the demand for a programming environment for the CMIF lab arose and the main project focus shifted to the concept-development, implementation and testing of the "CMIF HLA Environment".

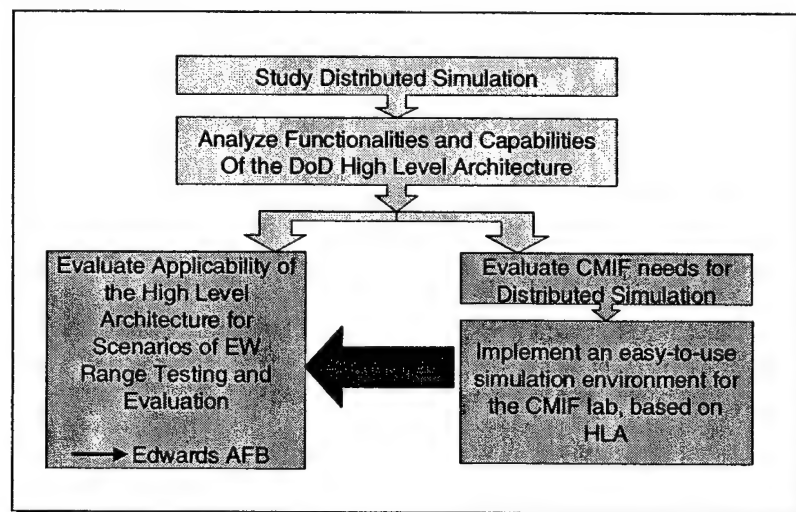

Figure 1.1: Purpose of this work: Two separate branches evolve but mutual benefits exist.

As depicted in figure 1.1, this leads to separate outcomes of this project which are not too apparently related to each other. The to be implemented lab environment for distributed simulation will be tailored to the needs of CMIF. Not neccessarily will it be applicable in other settings too. Nevertheless, the hands-on experience gained in dealing with distributed simulation in general and the Department of Defense High Level Architecture in particular will definitely be valuabe for further studies. Thus, the relevance of this research, and even the CMIF software, for the work done at Edwards AFB becomes evident.

The proceeding of this project was not fixed from the very beginnig, but rather did the work evolve over time, after more and more of the aspects and problems that are related to the High Level Architecture and to the distributed simulation field became clear.

Chapter 2

Issues of Distributed Simulation

In the following, after discussing the motivation for distributed simulation in general, several issues related to the overall field will be introduced. At this time, they might seem more or less unrelated to each other. But for the subsequent chapters, these topics will be needed as background information.

2.1 Motivation for Distributed Simulation

Previous research done by CMIF has already dealt with issues of distributed simulation. Software was implemented to simulate and study the behaviour of distributed data fusion nodes, multi-agent teams and the like. But always, the aspect of distribution itself had only been emulated. This meaning, the software “pretended” to deal with separate and independent components while, in fact, the whole simulation was carried out in one single computer program, one single process.

Figure 2.1: The step from emulated distributed simulation to “real” distributed simulation

Now the next logical step would be to try to do similar experiments in a “real” distributed environment, as it is suggested in figure 2.1. The components of one simulation experiment would run in various processes on different computers, connected by a local area network (LAN). But obviously this will introduce a number of disadvantages. Mainly, making this transition will lead to increased complexity due to

- the necessity of dealing with inter-process and inter-platform communications and
- synchronization and coordination issues between components.

At the same time though, also advantages arise with the transition to simulation that is in fact physically distributed:

- Increased computational power becomes available by utilizing the resources of several computers at a time.

- Due to the modular character, the reuse of components (especially support tools etc.) becomes possible and will, after an initially increased effort, make development more effective from project to project.
- Dealing with the additional problems of distributed simulation, and the resulting experience gain, will lead to knowledge advantages for subsequent work.

This makes clear, that the mentioned disadvantages can at the same time be viewed as positive aspects. And anyway, since real world systems are always distributed in one respect or another, there is no use in trying to get around the difficult issues that distribution entails. On the contrary: It is desirable to gain the expertise in dealing with distributed simulation while working in a small, manageable environment. Those lessons learned will then be readily available for subsequent and more advanced projects.

2.2 The Role of Time

When simulation components are implemented, which are supposed to work together in some kind of distributed simulation, among other things, a timing scheme has to be agreed upon. Timing can be handled in several different ways (ascending order of complexity):

Time is irrelevant. This would be true rather for technical simulations like FEM.

Time is relevant, but synchronization is only internal That means, although time is an integral part of the simulation behaviour, simulation time bears no

relation to real-time. Also, the simulation-speed or -rate can vary at the simulation's own discretion. An example would be the Canadian military simulation software CASE_ATTI [Cas00], which is also used in the CMIF lab. It features time synchronization between its internal components, but proceeds with the simulation execution always as fast (or slow) as system performance allows it.

Synchronized to time scale but slower than real-time: Each time step in the simulation is of equal length if measured in real-time, but simulation time proceeds slower.

Real-time synchronized: The simulation is fully following the real-time scale. This concept is of special importance, because only in this case can "Live Players" or real components be integrated into the otherwise virtual simulation environment¹.

Faster than real-time: If computing resources allow it, "fast-forwarding" through a simulation saves time, of course.

Figure 2.2 depicts these different approaches. It also introduces a scaling factor that relates the last three possibilities to each other, using the following formula:

$$Sc = \frac{t_{sim}}{t_{real}}$$

where Sc represents a scaling factor. If $Sc < 1$, we get slower than real-time behaviour, $Sc = 1$ represents real-time synchronization, and $Sc > 1$ leads to "fast forward".

¹Exceptions exist: Sometimes pilot training simulators are operated faster than real-time to induce a higher level of stress to the tested person.

Figure 2.2: Overview over different timing concepts

Before finally applying one of these three concepts for a distributed simulation, it has to be made sure, that the chosen scaling factor Sc is feasible for the given simulation workload and system resources. Otherwise, a simulation component might fall behind, timing might be lost and simulation results would then be rendered useless.

Another technical aspect related to simulation timing, is the question of timing control. It has to be determined, if one component will be responsible for the timing of others ("Master-Slave") or if each component takes care of timing itself.

2.3 Multi-Threading

Another important aspect that arises when dealing with advanced simulation, is *multi-threading*. In the programming world, the term thread is used for a part of a program that progresses with its flow of control basically on its own. Obviously, the term

became necessary only after computer systems and advanced programming languages became able to deal with more than one thread at a time. This is where multi-threading comes into play. Figures 2.3 and 2.4 show the basic difference: A computer program has to complete different tasks, and in the single-thread situation, this has to be done one task after the other. In the multi-threaded setting, in contrast, each task can be worked on in its own thread of execution.

Figure 2.3: Depiction of a single thread program execution

Figure 2.4: A program with multiple threads executing in parallel.

Threads can be used on a user-level, i. e. in application development, as well as on a system level (kernel threads).

The main advantages that multi-threading provides over single threads, are the exploitation of latency and concurrency. This means, that while with a single thread inherent waiting time of different tasks will add up, with multi-threading, latencies in one thread will be utilized for the execution of another task.

It must be mentioned, that multiple threads on a “normal” computer are never really parallel. They are just broken down into small segments on the system level. The execution of these segments is then switched between those belonging to different threads, making the tasks appear to be worked on in parallel. Of course, this is different with parallel-processor computers and with parallel computing systems.

As the two graphs suggest, difficulties with multi-threading arise because in most cases, threads are never totally independent from each other. They might access a pool of common data or directly interact with each other. The following problems come into play:

Data consistency: When different threads manipulate the same data, extreme caution has to be exercised. It has to be defined who is allowed to do what and at which point in time.

Dead-locks: Usually threads might interact with each other and thus affect their respective behaviour. Careful considerations have to be made about all possible states that a program’s task might be in when an interaction is attempted, to avoid illogical behaviour or dead ends in the execution. For example: Thread

one is waiting for input from thread two to proceed, and vice versa.

The mention of all these issues is not only important because the Run Time Infrastructure itself is highly multi-threaded and also the implementation of the CMIF HLA Environment will make use of several threads. Similarly, the concepts, advantages and disadvantages also apply to a multi-process situation and even to a multi-computer scenario of distributed simulation. In these cases, the same considerations about data consistency and possible dead-locks have to be made to ensure a smoothly performing system. That means, although the application developer who chooses to use the RTI and the CMIF HLA Environment maybe does not have to worry too much about internal threading issues of the provided software, he still has to keep in mind the same lurking problems and plan ahead to avoid them, also on an application level.

2.4 Time-Stepped versus Event-Based

This section addresses another central aspect of computer simulation. The question in this case is: What is the driving factor behind a simulation's proceeding, what stimulates the simulation to do its actual work? This leads to the following distinction²:

“Time-Stepped”: In this case, time is the driving factor behind the simulation.

Technically, the time is progressing in certain increments, and within each step, certain tasks are processed.

²The two terms are taken from the HLA terminology.

“Event-Based”: External input in the form of events is driving the simulation.

That means, the simulation reacts rather than acts.

In reality, simulation applications represent in most cases a hybrid combination of both behaviours. For example, a military flight simulator which mainly progresses with the simulation along the time-line, but also reacts to event-like pilot input or external events like “collision” or “missile fired”.

This way of looking at simulation behaviour is not necessarily limited to distributed simulation. But it is with distributed simulation, especially in the case of hybrid behaviour, that matters can get very complicated.

Chapter 3

The Department of Defense High Level Architecture

The best way to start an introduction to the High Level Architecture is to quote directly from the Department of Defense (DoD):

“The High Level Architecture (HLA) is a general purpose architecture for simulation reuse and interoperability. It was developed under the leadership of the Defense Modeling and Simulation Office (DMSO) to support reuse and interoperability across the large number of different types of simulations developed and maintained by the DoD.” [Def00b]

In what follows, a synopsis to the HLA will be given. Because plenty of detailed documentation about the HLA is available, and because a simple repetition of all this material was not desired, the overview will be kept brief. For further study the reader may be referred to [Def00b] and [JMP⁺99] and the DMSO website [Def00g].

3.1 Overview

The High Level Architecture (HLA) is a software architecture for distributed simulation. It can be used by developers to create simulation applications. When the HLA concept was developed, this was done before a background of a diverse environment that required extensive flexibility together with a minimum number of constraints. Military simulation applications cover a vast spectrum, from highly aggregated, discrete event simulators for the training of whole battle staffs to individual training simulators. And not only the training community relies on simulation, also the research and development communities have their own requirements for simulation applications.

So the HLA was developed to be flexible enough to cover this diverse set of simulation systems and sophisticated enough to embrace also the next generation of simulations [JMP⁺99]. The initial baseline definition of the HLA was done in 1995.

The HLA provides a technical framework to the developers that features a set of capabilities to support the design and execution of distributed simulations, composed of multiple simulation applications. In this context two key terms for dealing with the HLA are “**Federation**”, for the integration of a set of interoperating simulation applications and “**Federate**” for the single simulation component that participates in a federation. A participant in a federation could also be an interface with a live system, like a flight simulator or a telemetry unit for experiments on a testing range.

In figure 3.1 we can see a functional view of the High Level Architecture. As a technical framework architecture, it enables the integration of simulation federates,

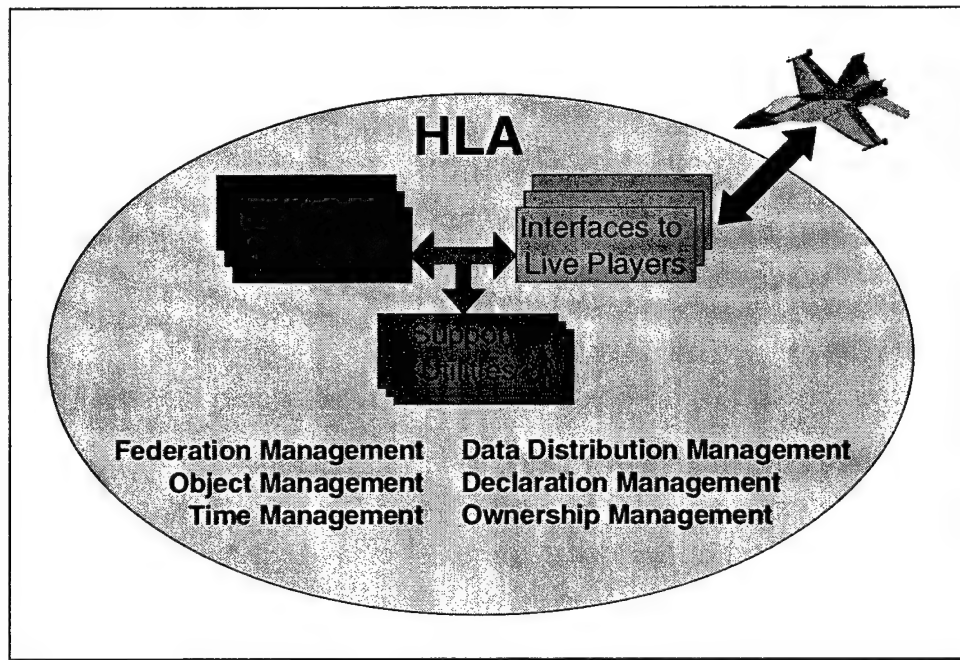

Figure 3.1: A functional view of the High Level Architecture

which can be genuine computer simulators, interfaces to “live” components and also support tools, into federations. This is done by providing definitions for:

- Federation Management
- Data Distribution Management
- Object Management
- Declaration Management
- Time Management
- Ownership Management

3.2 Simulation Interoperability and the Federation Development Process

When considering simulation interoperability, a distinction has to be made between two aspects of this field ([JMP⁺99]):

Technical interoperability refers to the issues related to actually making a federation of distributed and independent simulators work together.

Substantive interoperability addresses issues that impact on the ability of simulations to inter-operate in a coherent and logically meaningful way.

For example, the first item would include the definitions of inter-process and inter-platform communications, whereas the latter one would deal with questions like what data actually has to be exchanged between federates. Obviously, the two aspects are closely intertwined: Without interoperability on the technical level, the best substantive concepts cannot be put to work. At the same time, technical interoperability alone, without the substantive interoperability, is meaningless.

The HLA not only provides the developers community with the means to address the technical interoperability challenges, but also defines a process to organize and document the whole life cycle of the creation and execution of an HLA federation: The Federation Development and Execution Process, FEDEP. It comprises six steps:

Step 1: Define Federation Objectives

Step 2: Develop Federation Conceptual Model

Step 3: Design Federation

Step 4: Develop Federation

Step 5: Integrate and Test Federation

Step 6: Execute Federation and Test Results

3.3 The HLA Object Models

The architecture defines several object models, to standardize the development of HLA compliant software.

Federation Object Model (FOM): There is one FOM per federation and it introduces all shared information (i.e. Objects, Interactions). It also deals with inter-federate issues, e.g. data encoding schemes.

Simulation Object Model (SOM): The standard requires one SOM for each federate in the federation. It focuses on the federate's internal operation and describes salient characteristics.

Management Object Model (MOM): It defines all objects and interactions used to manage a federation.

Since especially the **Federation Object Model** will be of importance later in this work, we will go a little more into the details at this point. The first step to the implementation of HLA compliant software is the definition of the FOM. That means, everything that shall later be present in the "simulation space", has to be mapped

to the generic High Level Architecture constructs of Objects and Interactions. Both Objects and Interactions can have attributes to further refine the definition. Because an attribute to an Object can itself be an Object again, this leads to an object-oriented structure, where in the end everything is broken down to the level of generic simple data types (such as `String`, `int` or `byte`).

Both Objects and Interactions are of a similar nature. The difference is, that while Objects persist within the simulation space for a certain time (e. g. "Airplane", "Tank"), Interactions are instantaneous, non-persistent events (e. g. "Collision", "Radio Transmission").

The definition of the Federation Object Model is an enabling step, because it permits the sharing of information and the interaction between the federates, that will later be implemented. But it is also limiting, because only through the view defined by the FOM can federates "see" the simulation space and its other components.

To standardize the definition of the mentioned object models, the Object Model Template (OMT) exists. The OMT provides a common method for representing and documenting HLA object model information. Although the ideas of the Object Model definition process will be used all throughout this work, there was not no time to go through the detailed proceeding of using the OMT for definition and documentation.

3.4 High Level Architecture in real life: The Run Time Infrastructure RTI

The HLA serves as a theoretical framework, defining all necessary standards for the implementation of distributed inter-operating simulations. But there also exists an implementation that puts these concepts and interface specifications to work and provides common services to simulation systems –the Run Time Infrastructure, RTI.

Figure 3.2: Functional view of the Run Time Infrastructure – RTI

The RTI is provided to the developer as a software package that contains all necessary components to implement an HLA compliant simulation application and then to run whole simulation federations. The main components of the software package are:

- Class libraries that allow the developer to access the RTI services from his programs.
- Core system programs, through which all RTI inter-process communications

and interactions are handled. Concretely, these are the RTI background process `rtiexec` and the federation execution background process `fedex`.

Figure 3.2 shows, how these components work together: Linked by inter-process communications, we have several federates who access the RTI services by using the RTI programming interface¹. The figure reveals nothing about a possible spatial distribution, though. All the depicted components could be on different computers and operating systems. In that case, everything is interconnected by the local area network (LAN). Internally the RTI relies on TCP/IP for communications.

One of the central goals of the HLA, **simulation interoperability**, is ensured on a technical level by providing **platform interoperability** through the RTI. Currently, the runtime software is available for eleven different operating systems (e.g. Sun Solaris, Windows95, 98 and NT, Irix, Linux,...) and a variety of programming languages (C++, Java, Corba,...). A simulation application that is built on one operating system/programming language pair is technically able to join any federation, no matter which systems and platforms the other components rely on.

All RTI software, documentation and even supporting tools, is available from the Defense Modeling and Simulation Office (DMSO). It can be downloaded via the internet from their download server [Def00a]. But because this is military material, although not classified, some restrictions apply: Before being able to download and use HLA related material, the developer has to apply for a user account. Also, the RTI must not be exported outside the United States or given to anybody else by the approved user.

¹denoted by "libRTI" in the graph

This work is based on the “RTI Next Generation 1.3 Version 3.1”, which was effective during the implementation phase. In the meantime, the version has been advanced to 3.2.

3.5 The RTI and Timing

In the previous chapter, different concepts for simulation timing have been introduced. The Run Time Infrastructure can handle all these different concepts, which proves its versatility. Federations that do not deal with time at all can be implemented just as well as federations using highly sophisticated real-time synchronization schemes.

In general it can be stated, that each federate has its own understanding of time. There is no such thing as an universal, common simulation time. But the RTI provides means for the federates to coordinate their personal perception of time within the federation, based upon a scheme that has been agreed upon.

To implement the timing behaviour, federates can set two attributes, and by doing this, declare their own intentions and significance regarding the overall federation timing:

- **timeConstrained:** This only means, that the federate is bound to federation timing.
- **timeRegulating:** By declaring this, the federate states that other time constrained federates will be bound to this federate’s local time.

This allows for many possible combinations. For example, all federates could be

constrained and one of them additionally regulating, to implement something like a "Master-Slave" concept.

During the simulation, federates make known their intention of advancing their local time by posting a `timeAdvanceRequest` to the RTI services. According to the overall timing situation (i.e. how the before mentioned attributes are set and the other federate's times throughout the federation), the request is then granted by the RTI, as soon as it becomes feasible.

3.6 Applications for the RTI

Statistics of RTI downloads and of DMSO user accounts show that the RTI software is already being actively used by the military simulation community. Besides the HLA's formidable capabilities, one reason for this is most likely the Department of Defense policy to require all military simulations to be HLA-compliant by beginning of the year 2001. Although not everywhere could this deadline be met, it still makes clear the DoD's strong commitment to the HLA as the future foundation for all its simulation efforts.

As part of this work an attempt was made, to find out more about which simulation projects already use the HLA, to what extent and with how much success. However, with the author being a civilian, no detailed information about projects utilizing the HLA could be obtained. It seems though, that the efforts to incorporate the HLA are most advanced in the military training community. Different training simulators are interconnected to form whole battlespace training situations. Also the Joint

Warfighter Program builds on HLA compliance for its simulation efforts.

Now the applicability of distributed simulation and the HLA for CMIF's project partner, the Edwards AFB Range Testing Facility, has to be considered. Recent studies at CMIF proposed a distributed simulation environment as a necessary enhancement for EW range testing. The reason for this is, that the testing facility will soon be faced with testing aircraft-type systems whose basic employment concepts have them dependent on other system components. This means, that the airborne platforms, usually the actual hardware test-objects, are not really independent, but a part in a complex network.

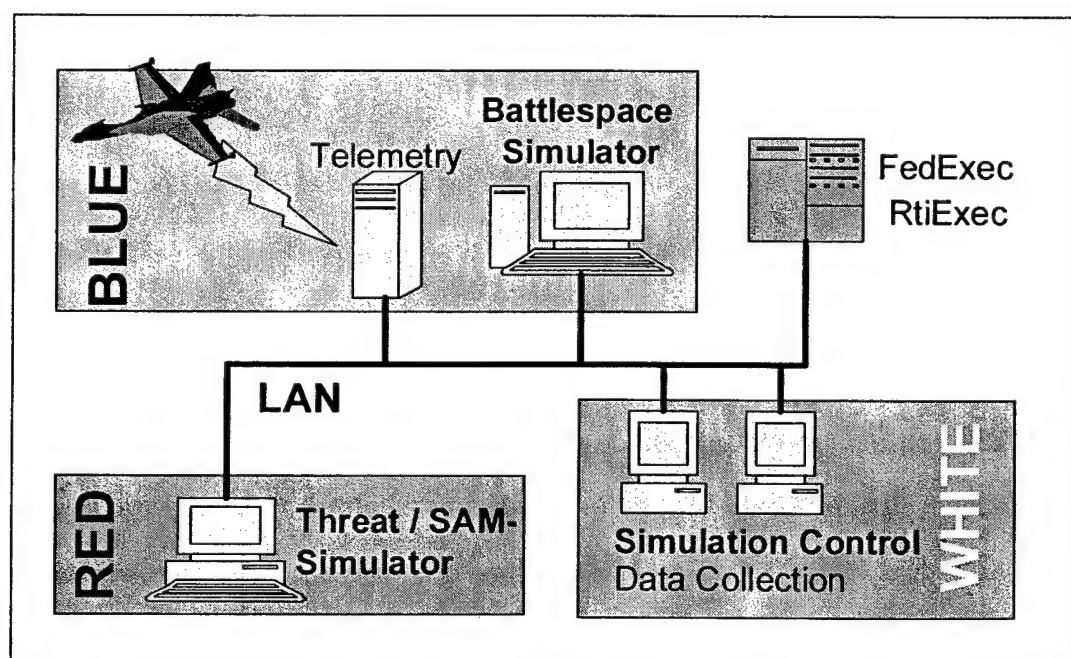

Figure 3.3: This scenario shows how in the future range testing could be enhanced by combining real (flying) components with virtual ones in one "simulation space".

Up to now, the range testing at Edwards is done in a one-on-one situation, where the to be tested EW component is subjected to stimulation by a single threat, a

hostile SAM system for example. This proceeding neglects the fact that today's battle scenarios resemble a network of interacting nodes, like fighters, AWACS radar surveillance airplanes, command and control posts, etc. And the same is the case for the enemy side as well.

Obviously it is not feasible to test a collection of full-scale system components. Thus driven by affordability concerns, a need for distributed simulation arises. Previous CMIF research proposes a Test and Evaluation (T&E) infrastructure based on a distributed simulation approach.

Figure 3.3 illustrates a possible future scenario for range testing, where the to be tested hardware is surrounded by an environment that is partly virtual and only partly real².

It must be understood though, that the proposed distributed, part-virtual environment will not be able to deal with the signal layer of the involved EW components. The virtual sections of the environment would in some way be limited to a higher level, and not deal with the very electromagnetic waves and signals, which are at the core of EW component testing. Simulations, which communicate themselves by means of electrical signals, would simply be too slow to emulate other high-frequency electrical signals. But because the same limitations exist for the connections between the real operational platforms, the simulated environment will still be able to contribute to the experiment and not be too far from reality.

²In this context, the following color coding is common in the military: "Blue" depicts the friendly side, whereas "Red" stands for foe. "White" denotes the environment perspective, meaning neutral observers, controllers and eventual supporting services.

Before this vague background it is rather difficult to make definitive statements about the applicability of the HLA for Edwards, or about the expenditure necessary to implement the proposed T&E Framework using HLA. So this section can rather be understood as a motivational scenario than as a technical concept.

Distributed simulation is not yet a fully mature science. There are many research issues to be considered in the course of defining the proposed T&E framework and the corresponding details before Edwards AFB Range Testing Facility will have sufficient knowledge and confidence to decide on an approach to implementing the framework. Thus there is a clear role for related university-type research to support Edwards in defining and designing the eventual framework approach to a new T&E infrastructure.

Chapter 4

The CMIF HLA Environment

4.1 Purpose of the CMIF HLA Environment

The Center for Multisource Information Fusion (CMIF) conducts research in various fields of distributed data fusion, target tracking and also multi-agent systems. A significant part of this work is usually done by single student or small student teams. Naturally, the personal commitment of an university student ranges rather over a couple of months than over several years, as it would be the case in a professional environment.

It would be desirable to utilize "real" distributed simulation, with all its before mentioned benefits, for the CMIF projects where applicable. But at the same time, the manpower available for these projects should not be wasted on familiarization with details of the RTI concept and implementation. Instead, the focus has to remain on distributed data fusion research.

The purpose of the CMIF HLA Environment is to bridge the gap resulting from the two goals introduced in the last paragraph: Make the RTI available to CMIF's research projects without requiring in-depth RTI knowledge or programming experience. Also, a reusable tool for simulation support is desirable, enhancing the simulation testbed with functionalities for simulation configuration, control and evaluation.

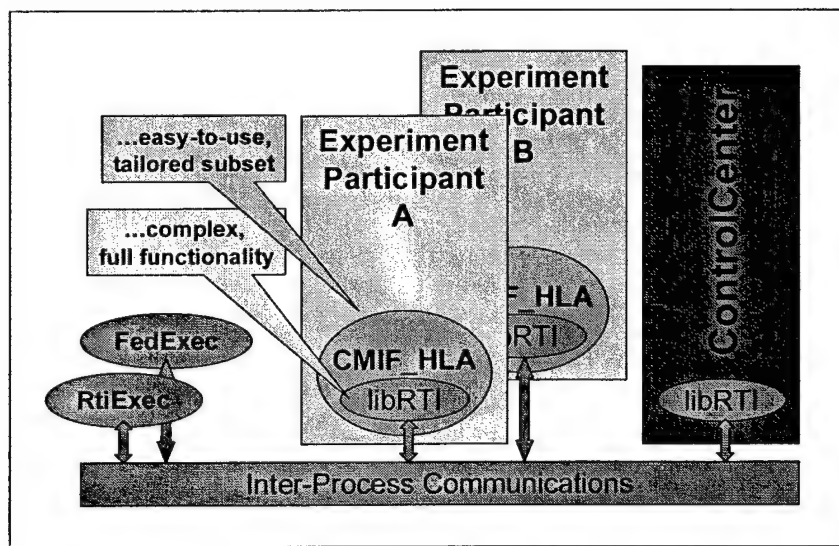

Figure 4.1: This graph shows a conceptual view of the CMIF HLA Environment. The complex RTI is masked from the developer of experiment participants by the CMIF programming toolkit, whose tailored functions are easier to use.

Figure 4.1 shows the concept of the CMIF HLA Environment. It is to be understood as a further development of the functional view to the Run Time Infrastructure from figure 3.2. Again we have several federates hooked up to the RTI services and thus populating one HLA defined "simulation space". But this time, the developers of the federates "Experiment Participant A" and "Experiment Participant B" do not

have to deal with the RTI Application Programming Interface (API)¹ but instead use the API provided by the CMIF HLA Environment. The CMIF API will ensure the following:

- The complex functionalities of the RTI are hidden from the application developer.
- Simple means for communication between experiment participants are made available.
- The functionalities of the supporting tool “control center” are accessible by a few simple method calls.

For technical reasons, a distributed simulation can never start right away with the pursuing of its simulation goal. Issues like establishing contact between the components and negotiation of key simulation parameters have to be taken care of first. In order to better organize this, the following set of six “Experiment Phases” was defined for the CMIF HLA Environment. Each phase requires a specific behaviour for the experiment participants as well as for the control center.

Phase I Configuration: This phase covers all steps necessary to configure an experiment within the CMIF HLA Environment. Defining which experiment participants will be present and setting timing parameters, for example.

Phase II RTI Setup: Initiation of contact to the RTI services, (in case of the control center:) launching the federation execution and establish contact between control center and experiment participants.

¹denoted by “libRTP” in respective graphs

Phase III **Simulation:** The experiment participants perform their actual simulation work, the control center provides the timing and other support services.

Phase IV **RTI Cleanup:** Orderly termination of contact to other federates and shutdown of the federation execution.

Phase V **Shutdown:** Cleanup and termination of the program itself.

Another phase could be "Simulation Postprocessing", following after the "Simulation" phase. It would cover everything related to the processing and evaluation of experiment results. Because no such evaluation functionality is implemented in the support tool "control center" so far, this phase was left out. An augmentation might later be necessary.

4.2 The Federation Object Model

This section refers to the definition of HLA object models as introduced in section 3.3. The Federation Object Model (FOM) contains the object-oriented definition of Objects and Interactions, representing the common view that all federates have of the simulation space.

To implement the CMIF HLA Environment, only two kinds of objects are necessary. They will be introduced from a FOM point of view at this point, but more detailed information will follow later in the according sections.

CMIFControlCenter

The control center will be the central federate within the CMIF HLA Environment,

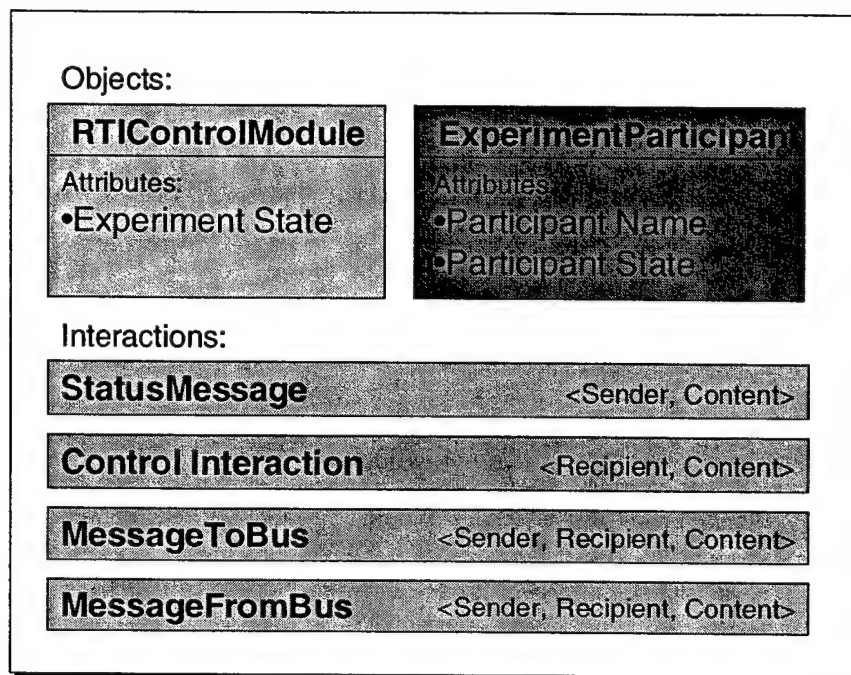

Figure 4.2: This graph shows the Federation Object Model for the CMIF HLA Environment with all objects and interactions, including their attributes.

responsible for all coordination and control issues. In the simulation space, it will be represented by the HLA object `RTIControlModule` (the nomenclature will become more obvious once the actual implementation of the control center and its class structure will be discussed). The only attribute to the control center will be `ExperimentState`, containing coded status information.

CMIFExperimentParticipant

Because the CMIF HLA Environment is again, very much like the High Level Architecture itself, a neutral testbed, it is not possible and desired to predefine what later participating federates in this environment will be like or what they will do. The only thing that is for sure is that they will interact with the control center and, of course, with each other. The first aspect refers to the environment's administrative

functionalities, whereas the latter one refers to the actual experiment content, the simulation specific behaviour.

Based on this, we introduce as an HLA object the generic `CMIFExperimentParticipant`. The only attributes necessary for the abstract experiment participant are `ParticipantName`, for identification, and `ParticipantState`, which will contain status and "health" information.

Also the following set of **interactions**, meaning: non-persistent objects, are defined for the CMIF HLA Environment:

- **ControlInteraction**: A means for the control center to control experiment participants. The two attributes are `Content` and `Recipient`.
- **StatusMessage**: This interaction lets the experiment participants send administrative information back to the control center. Attributes are `Content` and `Sender`.
- **MessageToBus**: The "Bus" represents the virtual communication line for inter-experiment participant communications, which are in reality routed through the control center. `MessageToBus` is a message issued by `Sender` for the `Recipient`.
- **MessageFromBus**: This is a `MessageToBus` after processing and rerouting by the control center.

All listed interaction attributes are of type `String`, whereas the status attributes of the two objects are of type `int`.

The definition of the Federation Object Model is the binding step, and since the RTI

relies on *late-binding*², all this is done by means of a federation configuration file that is interpreted at runtime. More precisely: at the initiation of the federation execution background process `fedex`. The file `CMIF_HLA_Environment.fed`, which defines the FOM for the CMIF HLA Environment, can be found in appendix B. While the `.fed` file also contains many higher-level parameters, the code that defines our specific objects and interactions can be found in two relatively small sections that are on pages 81 and 84. An overview to the whole CMIF HLA Environment FOM is given in figure 4.2. A more detailed description of the two major objects will be provided in the subsequent sections.

4.3 The CMIF Control Center

4.3.1 Overview

The CMIF control center is supposed to serve as a “White” control tool for experiments within the CMIF HLA Environment. Its main functions are to provide the user with control over and information about:

- experiment configuration,
- the simulation run,
- experiment participants present in the simulation space and

²This means, the definition of the object-structure is not hard-coded into the RTI software. While increasing the complexity, this is also the prerequisite for the RTI's high flexibility. The opposite concept would be *early-binding*.

- data collection for evaluation.

You could also think of the control center as an “operator’s desk” from where the simulation environment can be supervised. Some functionalities that are already integral parts of the CMIF HLA Environment concept, could not be implemented yet. Mainly these are: Data collection, evaluation of the amount of data being transferred between participants, emulation of communication “bandwidth” and advanced message routing. The implementation of these functions will follow with the next version of the CMIF HLA Environment package.

4.3.2 Class Structure

Because the implementation of the control center was a major part of this work, a few more details about its inner concept will be provided at this point. The control center’s functionalities are distributed over the following classes:

- **CMIFControlCenter**: The main class, linking all other components. It is responsible for startup of the program and initialization of all major components.
- **CMIFControlDisplay**: This class bundles all user interface functionalities. Display components are initialized and maintained.
- **CMIFExperimentManager**: The experiment manager is active during the configuration phase and handles all related tasks.
- **RTIControlModule**: This class is responsible for all activities related to the RTI. It establishes and maintains contact to all background services and to the

experiment participants during simulation setup and run.

- **RTIControlModuleFedamb**: The final interface class, linking the **RTIControlModule** to RTI services.

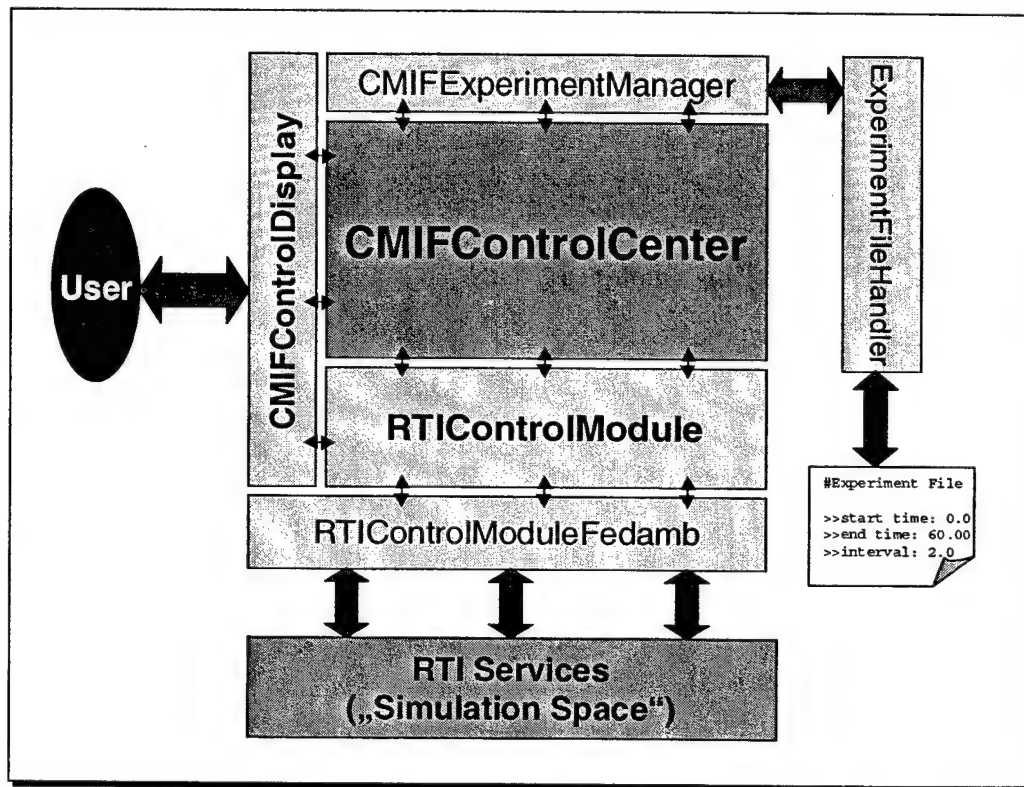

Figure 4.3: Overview over the control center class structure and interactions with outside components.

Also, some utility classes were developed, for example the classes **DebugHelper** and **ExperimentFileHandler**. The first one makes the output of debugging information (during development) easy and controllable. The latter one reads and writes the **.cef** experiment configuration files. See figure 4.3 for a depiction. The whole sourcecode can be found in the appendix, section D.1.

4.3.3 Graphical User Interface for the Control Center

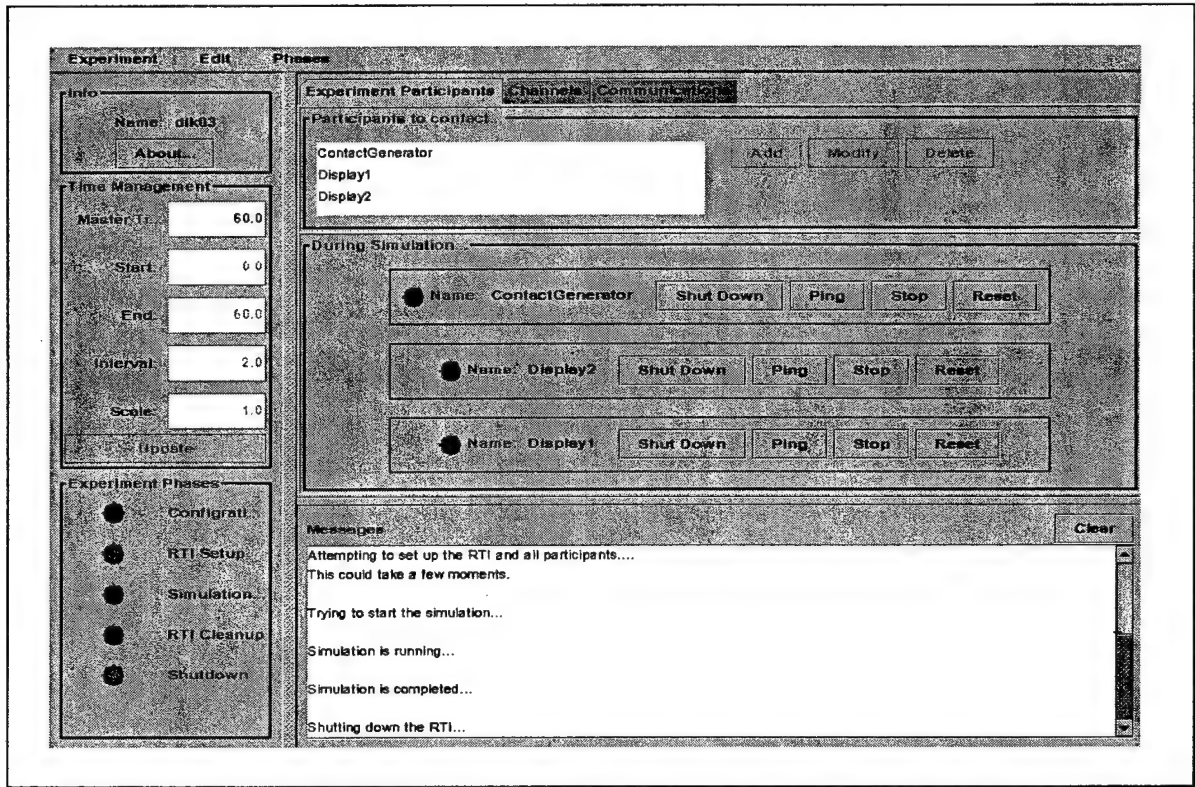

Figure 4.4: Screenshot of the complete control center user interface

Figure 4.4 shows a screenshot of the control center's graphical user interface (GUI). In the following, the main sections and their functionalities will be introduced.

Menus

In the current version, the control center contains two main menus, **Experiment** and **Phases**, offering the following functionalities: The **Experiment** menu contains items for handling the overall experiment configuration and the configuration files:

- New
- Open Old Experiment

- Close Current Experiment
- Save Configuration
- Save As...
- Exit

These should be more or less self-explanatory. `Save...` writes the `.cef` file and `Exit` terminates the whole control center application. The `Phases` menu lets the user switch between the before mentioned "Experiment Phases":

- Configure Experiment
- Setup RTI Execution
- Run Simulation
- Abort Simulation
- Clean Up RTI

A screenshot of both menus can be seen in figure 4.5

Info Panel

This panel simply shows the name of the current experiment configuration and allows to access additional information that has been stored about this experiment (see figure 4.6).

Timing Panel

This section of the graphical user interface allows to configure the timing parameters

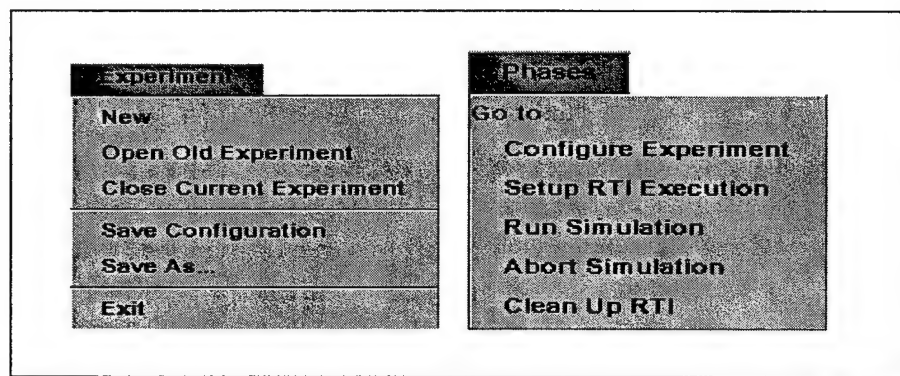

Figure 4.5: The control center Experiment and Phases menus

for the current experiment. On top, the master time, which progresses from start to end time during the simulation run, is displayed. The key values are: **Start**, **End**, **Interval** and **Scale**. The first two define the section of time that the simulation run will cover and the third sets the length of the time steps along which the time progresses. All three represent seconds. The last value defines the scaling factor which determines, how real-time and experiment time are related to each other (ref. figure 2.2). Changes in the timing section can only be made during the configuration phase and not while the RTI is being set up or the simulation is running (see figure 4.6). To make any changes effective, the **Update** button has to be pressed first.

Phases Panel

As a simple means for the user to see what state the control center is in at a given moment and what steps can/must be taken next, this panel shows the experiment phases together with colored icons. The icons have the following meanings:

- Green, blinking: This phase is currently in progress,
- Green, steady: This phase has successfully been completed,

Figure 4.6: This screenshot shows a close-up of the left side of the control center's user interface. It contains sections for experiment information, timing parameters and the simulation phases.

- Orange: It is possible to switch to this phase,
- Red: Switching to this phase is not possible.

Experiment Participants

Of the three panels situated on the upper right side of the main window, only one contains actual functionalities in the current version of the control center. The “Experiment Participants” panel has an important role in the control center's concept:

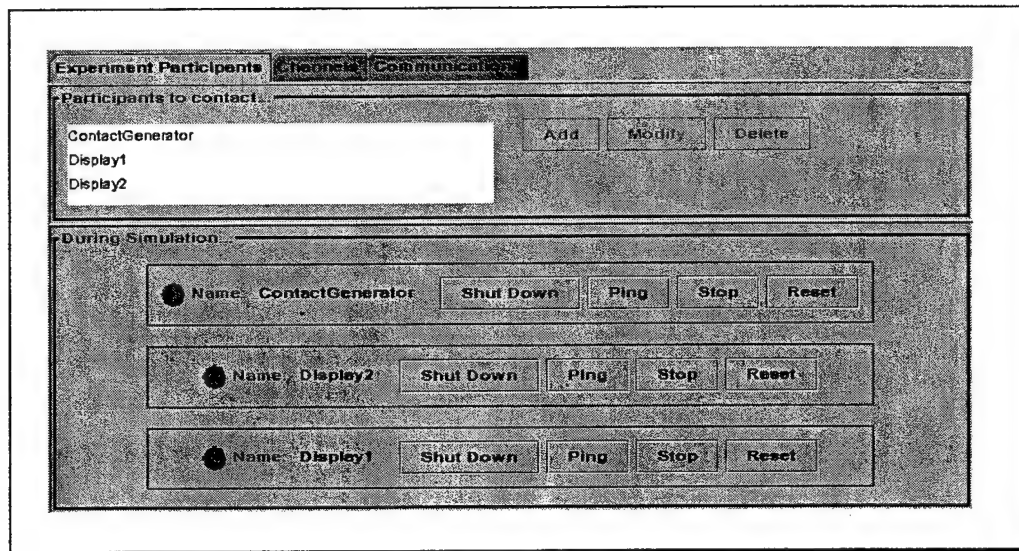

Figure 4.7: This section of the control center GUI informs about the experiment participants. The upper part represents the list of participants to contact, below is the dynamic representation of experiment participants during runtime.

Because the control center operates independently from experiment participant applications, the participants have to be contacted during runtime. Also, the control center does not “know” about what kind of applications will be present in the simulation space. So the user has to provide the control center with a list of all experiment participants that are to be expected. This is done in the upper part, where, during configuration, the user can add, remove and modify names on the “Participants to contact...” list.

The lower section (“During Simulation...”) is a dynamic representation of the control center’s perception of the simulation space. For every experiment participant that is discovered during the RTI setup phase, an information and control panel is created. It displays the experiment participant’s name, the current status (colored icon) and allows remote control via control interactions. These are triggered by using

the Shut Down, Ping, Stop and Reset buttons. The first two do work, the latter two have no effect in the current version of the software.

Only after the number of participants and their names in the lower, dynamic, list match the entries of the configuration list above does the control center declare the RTI setup phase for completed. See also figure 4.7.

Message Area

This area on the lower right side of the control center's window is used to display messages and feedback-information, errors, status, etc. – to the user.

4.4 The Experiment Participant

The other object that is defined by the CMIF HLA Environment federation object model is the `CMIFExperimentParticipant`. It is a generic representation of an arbitrary application that will in some way be involved in a distributed simulation experiment. This high level of abstraction makes it difficult to describe what the `CMIFExperimentParticipant` actually is, but reflects the very underlying concept: Think of what a distributed simulation with its components could be like and try to boil down their behaviour to a very general level. This leads to the statement, that all that any participant in a distributed simulation does, is the following:

- perform specific work, related to the simulation experiment,
- communicate with the other simulation participants as part of the simulated behaviour and

- communicate with the infrastructural services, support tools etc.

This can be interpreted as two separate levels: The *Simulation Level* deals with the actual purpose of the experiment, e. g. the tracking algorithms in a tracker component. Below that, on the *Administrative Level*, all the necessary tasks can be found that make the application actually participate in the distributed environment, negotiating timing and synchronization for example.

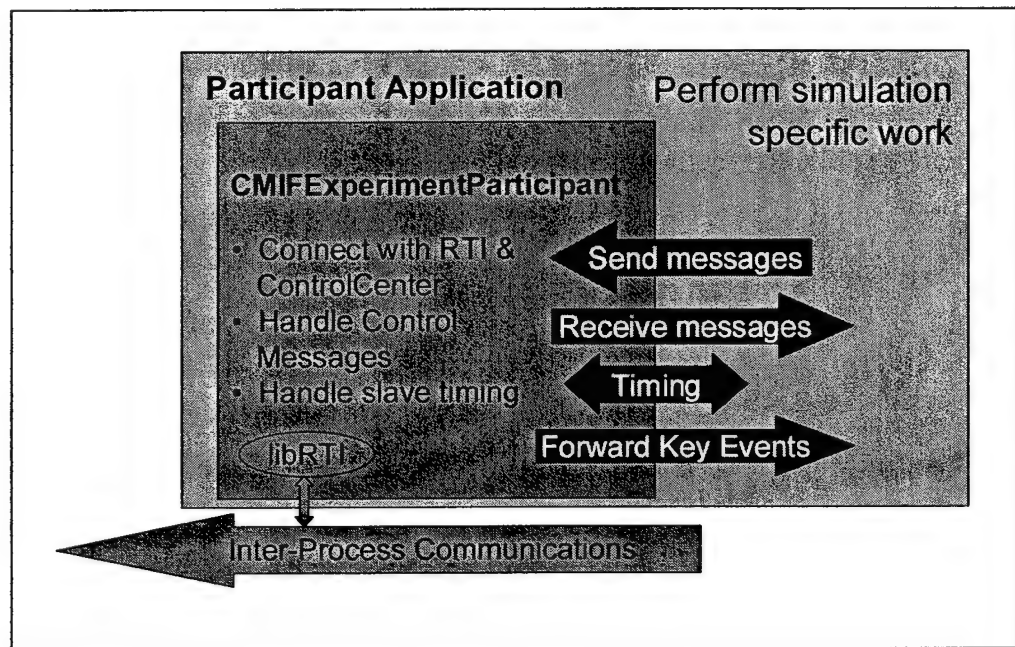

Figure 4.8: An overview over the experiment participant concept

Figure 4.8 visualizes how this concept is put into action: Any experiment participant application will subclass the generic `CMIFExperimentParticipant` and thus inherit its capabilities of dealing with the RTI services and communicating with the control center, the *Administrative Level* functionalities. Now the developer has to implement the simulation-specific behaviour to make his experiment participant actually do some-

thing. He also has to define the inter-participant communications, but does not have to go all the way down and work on the *Administrative Level* in order to do so. Instead, easy means for every contact with the “outside world” are provided by the `CMIFControlCenter` superclass.

From an HLA point of view, which brings us down to the *Administrative Level*, the experiment participant issues `MessageToBus` and `StatusMessage` interactions and itself is recipient to `Control-` and `MessageFromBus` interactions.

4.5 Implementation Remarks

For the implementation of the CMIF HLA Environment, the Java programming language was chosen. The main reason for this choice was the platform independency that Java provides. Code that is developed and compiled on one operating system will work on most other systems too (with some minor technical limitations, of course). With the CMIF lab’s computer network being a conglomeration of various operating systems and hardware platforms, using Java seemed like the only feasible approach for providing the lab with a usable software package for distributed simulation. Also while Java features all aspects of a high-level object oriented computer language, it is less error-prone (i. e. programmer’s errors) and is generally very suitable for prototype development. Last not least, with Java’s functionalities it is especially easy to develop appealing graphical user interfaces. A prerequisite was of course, that the run time infrastructure is available in a Java version, too.

The choice of Java also has some drawbacks:

- Subsequent development of applications will be limited to Java ³
- Java is not an ideal platform for the development of mathematical and numerical software and lacks a lot of functions in this regard. Add-on packages might be available, though
- The advantage of platform independency comes at the price of slower performance. Although this is a general problem of Java, no significant problems could be observed at the current stage of development of the CMIF HLA Environment.

³Theoretically, any other RTI supported language would be fine too, but that would require to start over at a deeper level and thus an in-depth knowledge of how the RTI and the CMIF HLA Environment work. Thereby, the initial goal of simplicity would be foiled.

Chapter 5

A Programmer's Guide: How to Install and Use the CMIF HLA Environment

This chapter is supposed to serve as a tutorial and programmer's guide for the implementation of distributed simulation experiments within the CMIF HLA Environment. It will cover all steps necessary, from installation of the software infrastructure over programming advice up to the actual execution of a simulation run. The latter two steps will be illustrated by guiding the user through the development of a sample program, the `DemoApplication`, which is part of the CMIF HLA package. Prerequisites for planning and implementing an experiment are knowledge of the Java programming language and familiarity with the specific operating system(s) for the installation process, because the RTI as a developer's tool is quite complex.

Please note that there will be no introduction on how to directly access the RTI within own code, because the whole purpose of the CMIF HLA Environment is to make this step obsolete for new users. Those who want to get into this highly complex area may be referred to the detailed documentation that comes with the RTI software ([Def00b] to [Def00d]). Also studying the commented source code of this work (see appendix D) or sample programs provided with the RTI can be extremely helpful.

5.1 Download and Installation of the RTI

Before using any part of the CMIF HLA Environment, a functioning installation of the Run Time Infrastructure is needed on all platforms and computers that will be used in an experiment setup. Because a very detailed description of the process, also addressing the different platforms, can be found in the "RTI Installation Guide" ([Def00f]), the following list covers the proceeding only in brief:

Download the Run Time Infrastructure software from the DMSO server at <http://sdc.dms0.mil>. This requires to obtain a user account first. The software is provided for different platforms and programming languages from which the user can choose the appropriate configuration. There usually are installation prerequisites, like the presence of certain C-libraries or C-compilers on the system, but these prerequisites are well documented.

Note that the RTI implementations in programming languages other than C++ are usually add-ons to the C++ core system. For example, for the CMIF HLA Environment (which uses Java), the C++ as well as the Java package have to

be downloaded and installed. The specific packages used for this work were:

RTI-1.3NGv3.1-SunOS-5.6-Sparc-SPRO-4.2-opt-mt.sh and
RTI-1.3NGv3.1-SunOS-5.6-Sparc-SPRO-4.2-opt-mt-JavaBinding.sh.

It can be seen, that even the name of the download file reveals the key information about the specific configuration.

Unpack the software to a suitable directory, the core and the Java packages to the same one. The RTI packages usually come as self extracting executables (.exe and .sh) or have to be unpacked using the ZIP (Windows) or the gunzip and tar (UNIX) utilities. The resulting directory structure after unpacking is standardized for all RTI versions and can be seen in figure 5.2.

```
...
#RTI variables:
export RTI_HOME=/home/kharth/HLA/RTI-1.3NGv3.1
export RTI_BUILD_TYPE=SunOS-5.6-Sparc-SPRO-4.2-opt-mt

export LD_LIBRARY_PATH=
    $LD_LIBRARY_PATH:$RTI_HOME/$RTI_BUILD_TYPE/lib

#RTI Java
export JAVA_BINDING_HOME=
    $RTI_HOME/$RTI_BUILD_TYPE/apps/javaBinding

export CLASSPATH=$CLASSPATH$JAVA_BINDING_HOME/classes:.
export LD_LIBRARY_PATH=
    $LD_LIBRARY_PATH:$JAVA_BINDING_HOME/lib
...
```

Figure 5.1: Sample configuration file .bashrc

Adjust the environment variables. The RTI relies on this mechanism to facilitate the management of different RTI versions or configurations in one filesystem. The variables point to the directories where the system files are to be found and the following settings are needed:

- `RTI_HOME` – set to the directory where the RTI is installed
- `RTI_BUILD_TYPE` – set to the installation specific build type
- `JAVA_BINDING_HOME` – directory where the RTI Java classes can be found
- `LD_LIBRARY_PATH` – path to shared object libraries (UNIX specific), both C++ and Java
- `CLASSPATH` – path to Java classes

Under UNIX these settings are usually defined in the `.bashrc` or `.aliases` configuration files. See figure 5.1 for a sample section of such a file. On Windows platforms the approach is slightly different, please refer to [Def00f].

Modify the configuration file `RTI.rid`. This file contains important system and networking settings for the RTI. For now, one parameter has to be defined: Open the file in a text editor and change the setting for `RtiExecutiveEndpoint` to the hostname (and port number) of the computer that will be running the RTI background process later. The port number is a five digit number that is arbitrary as long as it does not interfere with any other service that is using the network. If all components of the experiment will be running in different processes on the the same computer, the line can be commented out all together. See appendix A, line 4, for a sample setting. You can keep several `RTI.rid`

files with different settings. When, during runtime, the federation execution is created (`fedex` process), the program always looks for the file automatically in the same location from where the control center was launched.

5.2 Installation of the CMIF HLA Environment

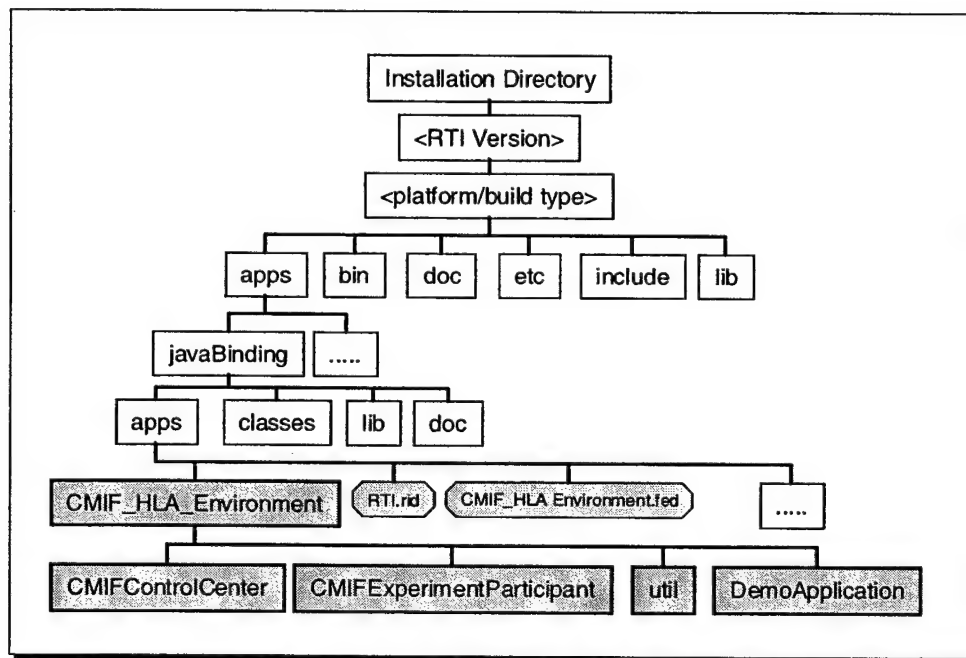

Figure 5.2: This graph gives an overview over the directory structure of the CMIF HLA Environment. White boxes indicate a common RTI installation, grey indicates parts of the CMIF HLA Environment.

The latest version of the CMIF HLA Environment can be obtained from the author. You will receive either a `.zip` (Windows) or `.tar.gz` (UNIX) file which has to be unpacked into the directory `$JAVA_BINDING_HOME/apps/`. The resulting directory structure, which is added onto the common RTI installation, can be seen in figure 5.2. The directory `CMIFControlCenter` contains all the classes that belong to the Control

Center whereas `CMIFExperimentParticipant` contains all classes of the generic experiment participant. Parallel to the `CMIF_HLA_Environment` directory, the two RTI configuration files can be found: `RTI.rid`, defining networking and system parameters, and `CMIF_HLA_Environment.fed`, the file defining the federation, its objects, interactions and attributes (see appendices A and B). This also is the point from where CMIF HLA related applications have to be started.

The current version of the CMIF HLA Environment has been developed and tested under Sun Solaris 2.6, using the "RTI-1.3 Next Generation Version 3.1". Also a test under Linux (Debian 2.2) has been successful. Normally the software should also work on other platforms or with newer versions of the RTI, but limitations may exist.

For the Java programming, a Java Software Development Kit (SDK) for Java 2 is needed which supports Java native threads. For details see the Sun Microsystems website at <http://www.sun.com>.

5.3 Implementing an Application

What follows is the description how to actually implement own experiment participants or "agents" that can form an experiment within the CMIF HLA Environment. This is the point where the transition from the abstract *early-binding* stage to *late-binding* is made and the generic experiment participant is developed into an application with specialized behaviour.

The main step to make all services accessible to an application is to subclass the generic `CMIFExperimentParticipant`. This class masks all low level communication

with the RTI from the developer and provides two-way interaction with the rest of the system by means of the inheritance principle: The application can act by calling methods provided by and inherited from its superclass. At the same time it can react through the callback concept. "Callback" means, that during program execution, the super class will invoke methods that are empty on the superclasses level itself. Only if they are overridden in the subclass and given any specialized behaviour, something actually happens.

5.3.1 Programming Toolkit Overview

5.3.1.1 Setup

In this case, "setup" means the initialization of the contact to the Run Time Infrastructure and, after that has been accomplished, the contact to the control center. The key steps are as follows:

1. Establish contact to and join the `CMIF_HLA_Environment` federation execution.
This of course means, that it must already exist. The federation execution is created by the control center, during the RTI setup phase.
2. Report to the control center and exchange status information.
3. Receive key simulation information (i. e. timing) from the control center.

These tasks are processed in the background. All that has to be done at the application level to get started is to call the method

`doSetup()`.

This does not necessarily have to be at the beginning of the program, just prior to any RTI related activity. The setup process is executed asynchronously in its own thread, which means that the call to `doSetup()` returns almost immediately and other things can be done. The applicataion is then notified of the succesful completion of all setup tasks by a callback to

`doneWithSetup()`.

Furthermore, a callback to

`timingParametersChanged()`

indicates, that the timing parameters (i.e. start and end time, increment and scale-factor) have been set after negotiation with the control center. After these steps, the application has nothing to do except to wait for the signal from the control center that the simulation run has started. This is accomplished by calling the method

`waitForSimulation()`,

which puts the execution on hold until the next phase becomes active.

5.3.1.2 Simulation Run

As discussed earlier, there are two major paradigms for federate behaviour: Time-Stepped and Event-Based.

A Time-Stepped application will follow the simulation timeline and somehow determine its actions based on the current time. To implement this behaviour, the following concept is needed: After simulation start, the program has to enter a `while`-loop. At one time within the loop, a call to the method

`advanceOneStep()`

has to be made to force the federate to the next step in time (old time + increment).

Alternatively, a call to

```
advanceTo(double newTime)
```

overrides the time increment parameter and attempts to jump directly to `newTime`.

The call to one of these methods does not return until the desired new time is feasible, which means synchronous to the control center's master time. As a condition for the while-loop,

```
boolean simIsRunning()
```

can be used, which returns true or false to indicate if the simulation is still in progress.

Furthermore, with

```
double getTime()
```

the current federate time can always easily be obtained.

The whole thing will look like this:

```
while ( simIsRunning() ) {  
    //do something...  
    //...and something else  
  
    advanceOneStep();  
}
```

An experiment participant with Event-Based behaviour is much easier to implement. Nothing special has to be done. The processing of incoming or outgoing messages and interactions is already ensured by an independent background thread. Any action will really be a reaction to some kind of input, live user/"player" or message. The means and methods for processing incoming interactions to the application will be discussed in the next section. Time, in this scenario is disregarded.

The most likely and realistic case however will be a combination of both Time-

Stepped and Event-Based behaviour, which requires a very careful approach. All situations where one part could block out the other one have to be strictly avoided. For example, the program might be lying dormant to wait for user input and, while doing so, not perform the time-stepped tasks. Other available methods and callbacks related to the simulation run are

- `doneWithSimulation()`: Another notification that the simulation run is over. This can be used in Event-Based experiment participants, because these would not have the simulation `while`-loop.
- `updateSimTime(double simTime)`: Whenever the simulation time has successfully been changed to a new value, this callback method is activated.
- `abortSimulation()`: Notification that for some reason the simulation has been aborted.

5.3.1.3 Communications

This section deals with the methods and callbacks that are involved when communicating with the “outside world”, i.e. other experiment participants or the control center. All data exchange is done with `String` data types. For details how to convert other data types to and from `String` representation, please refer to the Java API Documentation [Jav00b], classes `String`, `StringBuffer`, `Integer`, `Double` etc.

The following methods are responsible for **outgoing messages**:

- `sendMessageToBus(String message, String recipient)`: A message to the imaginary communications “bus” that the experiment participant is connected

to. First it goes to the control center for evaluation and logging, and from there it is distributed to the final recipient (which can also be “all”, in order to reach all present participants).

- `sendMessage(String message)`: Status messages can contain data for experiment evaluation. They are simply sent to the control center and written to the log file.

And in the opposite direction, **incoming messages**:

- `receivedMessageOnBus(String sender, String content)`: Callback method, delivering a message from another experiment participant, the sender.

5.3.1.4 Multi Threading Problems

In the way presented above, the experiment participant functionalities are only suitable for applications that do not perform heavy computational tasks. If that were the case, all tasks that are also running in the main thread, will be slowed down or even halted, because the main thread is also where the actual “simulation work” of the application is done. The most common occurrence of this problem is when the display “freezes” and thus behaves strangely: Buttons do not react, menus stay open instead of collapsing or other obsolete information is being displayed. The interaction with the “outside world” (i.e. all RTI related business) however will not be affected because all related tasks are already provided with their own threads.

These issues are not resolved easily and it has to be considered whether the CMIF HLA Environment is the right testbed for “number crunching” applications, anyway.

Nevertheless, there is one possibility how to decouple the simulation task from from the GUI related work and thus make the display perform smoothly without in-depth knowledge of Java threads programming. The utility class `SwingWorker` (see appendix D.4.3) provides an easy means for using an additional thread to keep the display from halting. Just place the following code wherever the new thread is needed:

```
final SwingWorker worker = new SwingWorker() {
    public Object construct() {

        //...code that might take a while
        //to execute is here...

        return null;
    }
};
worker.start();
```

The call to `worker.start()` initiates the new thread execution, but then immediately returns from the call and continues in the old thread. An extra thread can be very convenient, but the following limitations exist: From inside the new thread you cannot perform any GUI related work, except for calls to `Container.revalidate()`, `Component.repaint()` because only those are handled in a thread-safe way.

There are much more functionalities to the `SwingWorker` class, though. A detailed description can be found at [Jav00a], under `/uiswing/misc/threads.html`.

5.3.2 An Example: ContactGenerator and TacticDisplay

To do a "Proof-of-Concept" for the CMIF HLA Environment implementation, as well as to evaluate handling of the control center and test system performance, two demo

applications were implemented. First, the functionalities of the `ContactGenerator` and `TacticDisplay` will be described. Then it will be shown how the concepts, methods and callbacks which were described in the last section, are actually put to work in “real” applications. However, the `ContactGenerator` as well as the `TacticDisplay` do not contain any functionalities related to actual distributed data fusion.

5.3.2.1 The TacticDisplay Application

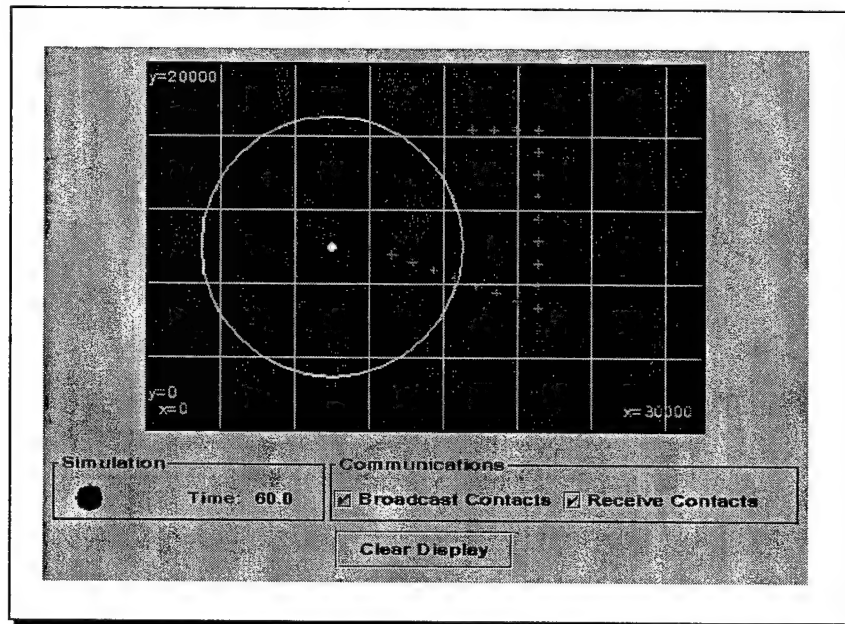

Figure 5.3: Screenshot of the TacticDisplay application user interface

The `TacticDisplay` resembles a simple radar display. Its user interface features a radar screen with 2-D coordinates. Within the rectangular display area, a yellow circle indicates the imaginary “radar range” of the `TacticDisplay`. During the simulation run, the application reacts to incoming messages, which resemble position reports. First-hand radar contacts are reported to the application in the following way:

`ContactX=#11705#Y=#2342#.`

The program now evaluates if an incoming report falls within the range of its own radar, if it can actually “see” the target itself. If that is the case, the position report is displayed on the screen with a red x. Furthermore, any `TacticDisplay` also shares known contacts by rebroadcasting them with a message like this:

`ReportedContactX=#11705#Y=#2342#.`

Any other `TacticDisplay`, which is present as an experiment participant, will display such a second-hand report with a grey +, no matter, if the position falls into its own reception range or not.

In addition, the application also has a “Communications” panel which lets the user toggle the behaviour regarding the broadcasting and the evaluation of second-hand reports. The “Simulation” panel just displays information about the state of the simulation run and the current federate time. A screenshot of the graphical user interface is shown in figure 5.3.

5.3.2.2 The ContactGenerator Application

As the name suggests, the `ContactGenerator` provides the `TacticDisplays` in the simulation space with the mentioned first-hand contact reports. To come up with these, it lets the user “fly” an imaginary “airplane” across the 2-D plane. The user interface again has a 2-D display area on which the current and former positions of the airplane are depicted. The flight path is determined by entering (and dynamically altering) values for the parameters `X Position`, `Y position`, `Velocity` and `Heading` in the according textboxes. Like in the `TacticDisplay`, the “Simulation” panel

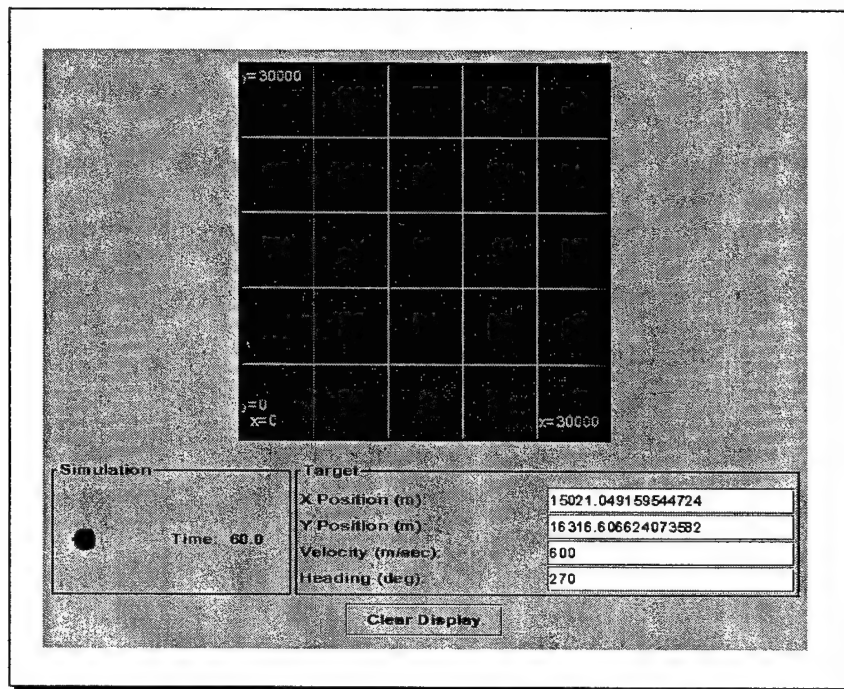

Figure 5.4: Screenshot of the ContactGenerator application user interface

informs about simulation state and progress of time. A depiction of the user interface can be seen in figure 5.4.

5.3.2.3 Implementation

The full sourcecode for both the `TacticDisplay` and the `ContactGenerator` class can be found in the appendix, sections D.3.3 and D.3.1, respectively. At this point however it will be shown, how the methods of the CMIF HLA Environment are to be used and implemented, in order to show the developer how to approach the implementation of own experiment participants.

First of all, the CMIF HLA Environment packages have to be made accessible using the import declarations at the beginning of the code:

```
import CMIF_HLA_Environment.CMIFExperimentParticipant;  
import CMIF_HLA_Environment.util.*;
```

Then comes the class declaration, also defining, that the new class is a subclass to the abstract class `CMIFExperimentParticipant`:

```
public class ContactGenerator  
    extends CMIFExperimentParticipant
```

The static method `main(String argv[])` is always called by the Java virtual machine at the start of any application. Command line arguments, if any, are passed in the `String` array `argv[]`. Because we want an object instance of our application, we create it right there, using the `new` operator:

```
public static void main(String argv[]) {  
    ContactGenerator instance =  
        new ContactGenerator(argv);  
} //end of main
```

Now follows the constructor, which could be considered the start-up method of the object instance. The first method call has to go to the constructor of the superclass, using `super()`. In this case, `CMIFExperimentParticipant` is the superclass and it expects one `String` argument, the name of the specific experiment participant by which it later will be identified within the simulation space. For the `ContactGenerator` the name is fixed, whereas the `TacticDisplay` adapts the first command line argument as its name during startup.

```
public ContactGenerator(String[] argv) {  
    super("ContactGenerator");  
    ...  
    ...
```

Now, still at the beginning of the code, the crucial steps to get involved with the rest of the simulation space follow like this: First the setup phase is initiated and then, while that is taken care of asynchronously in the background, the method `createDisplay()` is called. This method is application specific and contains the code to put together and initialize the graphical user interface. With Java and Swing, Java's GUI toolkit, this itself can take some time and might be rather slow. Normally, a callback from the superclass (`doneWithSetup()`) indicates when the setup phase has successfully been completed, but since we do not need to do anything special in that case, we just enter the method `waitForSimulation()`, which holds the program execution until the control center gives the signal that the simulation run has started.

```
...
...
doSetup();
createDisplay();
waitForSimulation();
startSimulation();
} //end of constructor
```

Everything that has to be done during the run, has been moved to the method `startSimulation()`. In our case, `ContactGenerator` is the Time-Stepped simulation component, because once during every step it will calculate a new position for the imaginary airplane based on the old position and the current settings of the textboxes. The new position will then be displayed and sent out as a message. All this is done within a `while`-loop which executes for the duration of the simulation. At the end of each `while` iteration, the call to `advanceOneStep()` ensures, that the simulation time is being advanced. So the simulation method contains the following code:

```
public void startSimulation() {
```

```
...

while (simIsRunning()) {

    determineNextPosition();
    displayPanel.repaint();
    sendContactPosition();
    advanceOneStep();

} //end of while loop
} //end of startSimulation
```

The `TacticDisplay` is by its nature, i.e. reacting to external input, an Event-Based experiment participant. Nevertheless, it too has the characteristic simulation `while`-loop, but the only task of this loop is to follow the simulation time and correctly display it for the user.

Now we will have a closer look at how the communications are taken care of. Whenever a message is delivered to a `TacticDisplay`, this is done by a callback to the following method:

```
public void receivedMessageOnBus(String sender,
                                String content) {

    //first dissect the message content
    //and store the coordinates in a point

    //...if it is a first_hand contact: test if in radar range
    boolean isWithinRange = evaluateRadarRange(contactPoint);
    if (isWithinRange) {

        //add to the list of previous first-hand contacts
        //(used for drawing the x's)
        radarContacts.add(contactPoint);

        //and rebroadcast the same position report, only
```

```
        //with "Reported" added to the message header
        sendMessageToBus("Reported"+content, "all");
    }

    //...if it is a second-hand contact, add the point
    //to the list of previous second-hand contacts
    //(used for drawing the +'s)
    reportedContacts.add(contactPoint);

} //end of receivedMessageOnBus
```

The code snippet has been abbreviated to show only the important steps. Most interesting is firstly how to generally fill the `receivedMessageOnBus` method with life and secondly how to use the `sendMessageToBus` method, in this case with "all" as the desired recipients for the message. That means, also the `ContactGenerator` will get the message, only that it will not evaluate and use it, since it does not have an overridden version of `receivedMessageOnBus`.

In both applications, the other callback methods —`updateSimTime()`, `timingParametersChanged()`, `doneWithSimulation()`, etc.— do not do much except to force the user interface to show updated information on the "Simulation" panel.

Last not least, the callback indicating that the contact to the RTI services and therefore all other experiment participants has successfully been terminated, leads to the final shut down of the application.

```
public void doneWithShutDown(){

    mainWindow.dispose();
    System.exit(0);

} //end of doneWithShutDown
```

5.4 Putting Everything to Work:

A Simulation Run

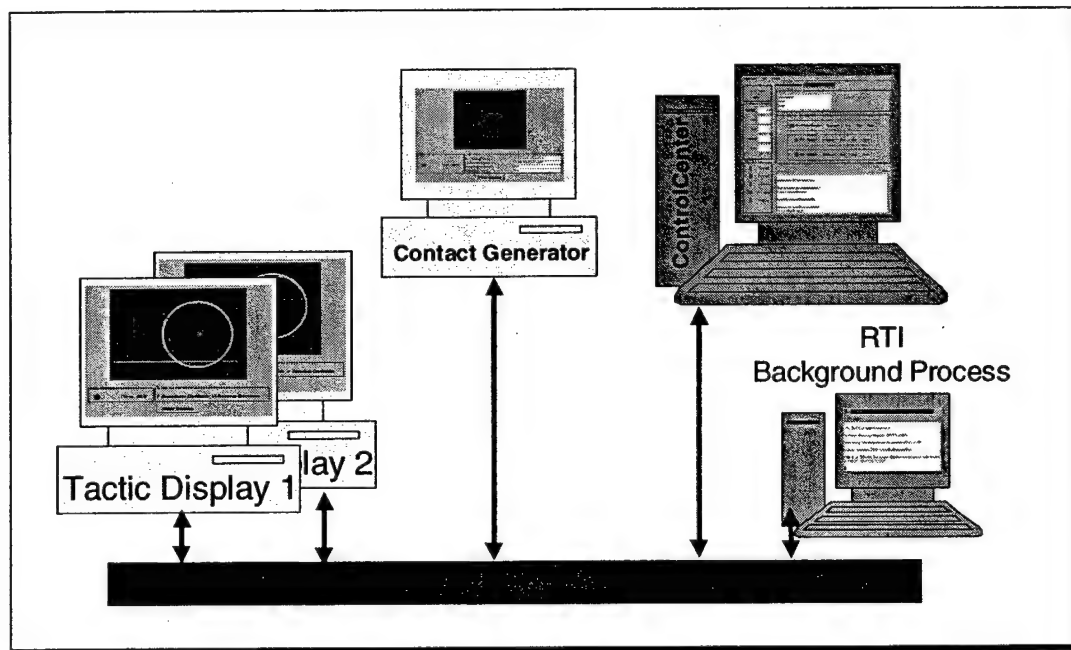

Figure 5.5: Structure of the demo application

In the previous section, the implementation of two experiment participants was discussed. Now it will be shown, how these applications are started and, together with the other components of the infrastructure, are integrated into the simulation space to form an experiment setup. Then, we will go through the actual process of conducting a simulation run, step by step from startup to shutdown. Whenever specific commands are listed, these apply to using the CMIF HLA Environment on the UNIX (or Linux) platform. The general handling of the system is not different for the Windows operating systems, although minor adjustments have to be made.

As can be seen in figure 5.5, the configuration will feature one `ContactGenerator`

and two `TacticDisplays`. These will both have the same display area, but different areas of "radar reception" so that the benefit of their data sharing behaviour can be observed. Also present, of course, will be the RTI background services as well as the control center. All components will be interconnected through the local area network.

The first step for running an experiment within the CMIF HLA Environment is always to start the RTI background services. This is done by starting the `rtiexec` process on one of the computers that are involved. Just type

```
kharth@kadar> $RTI_HOME$RTI_BUILD_TYPE/bin/rtiexec  
-endpoint <hostname>:<port number>
```

at a command line prompt. The parameters `<hostname>` and `<port number>` of the `-endpoint` option must hereby match those defined in the `RTI.rid` file or an error will occur (see section 5.1). It can also be useful to define a shortcut for this, because this line will be used quite often. As a result, the RTI services are initialized and remain in the background for all federates to use. The `rtiexec` is textbased. After startup it displays only messages about created and destroyed federation executions and joined or leaving federates. Also, system level error messages are shown, in case something goes wrong. See figure 5.6 for a sample output of `rtiexec`.

Now the control center has to be started, prior to all experiment participant components, to work on the experiment configuration and later, start the federation execution. First change to the root directory of the CMIF HLA Environment:

```
kharth@kadar> cd $JAVA_BINDING_HOME/apps
```

(or add that path to your Java environment variable `CLASSPATH`, for convenience) and then start Java:

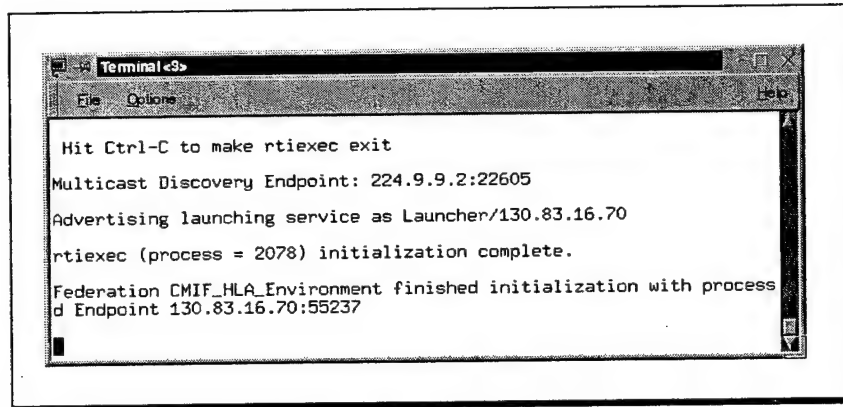

Figure 5.6: Before experiment participants and the control center can hook up with each other, the background process of the RTI, *rtiexec*, has to be present. It is launched from the command line of a terminal window.

```
kharth@kadar> java -native CMIF_HLA_Environment/  
CMIFControlCenter/CMIFControlCenter
```

Phase 1: Configuration

Once the main window appears, the experiment configuration can be begun: Open a new experiment, using the menu **Experiment>New**, or alternatively, open an existing one with **Experiment>Open Old Experiment**. If you chose **New**, you will be prompted for an experiment name and a short description. While the latter is optional, the name will also be used as a file name for saving the configuration.

The most important step is to define the list of experiment participants to be expected in the simulation space. Because the control center is supposed to be independent of specific experiment setups, it can only be informed at runtime, which applications will be participating, in order to contact and address them properly when they arrive in the simulation space. We do this by simply adding the names of the desired experiment participants to the "Participants to Contact" list. This time it

will be ContactGenerator, Display1 and Display2.

Now we will adjust the experiment timing parameters for our purposes by simply editing the textboxes in the "Time Management" panel: Let us choose 60.0 seconds as a new end time for the simulation and set the time step increment to 2.0 seconds. Important: Changes do not have any effect until the "Update" button is clicked.

With the configuration now completed, the settings can be saved using the menu item Experiment>Save. The experiment configuration file (.cef) belonging to this specific configuration can be found in the appendix, section C. Note that all the time the ongoing configuration phase has correctly been indicated by the blinking green icon in the "Phases" panel.

Phase 2: RTI Setup

By switching to the next phase (menu: Phases>RTI Setup), the user initiates the following actions:

- The control center creates the federation execution **fedex** process for the CMIF HLA Environment. It also joins the federation (and thus the "simulation space") as the first participant.
- Now the control center waits for other federates to become present, asks for their names and compares them to the list of experiment participants to be contacted.
- Once all the expected experiment participants are located, contacted and have reported ready for simulation, the control center declares the RTI setup phase for complete.

This is the point where all other experiment participants have to be launched. Generally, these are independent from each other and from the control center. They run in separate processes and can (and in fact should) be located on different computers. The only rule is, that any experiment participant's `doSetup()` must not be called before the control center initiated the federation execution, because the experiment participants just rely on the fedex to be present. Now we can type (in different terminal windows or on different machines):

```
kharth@kadar> java -native CMIF_HLA.Environment/  
CMIFExperimentParticipant/ContactGenerator
```

```
kharth@ming> java -native CMIF_HLA.Environment/  
CMIFExperimentParticipant/TacticDisplay Display1 0 0  
30000 20000 10000 10000 8500
```

```
kharth@joker> java -native CMIF_HLA.Environment/  
CMIFExperimentParticipant/TacticDisplay Display2 0 0  
30000 20000 20000 10000 8500
```

Here is a key to the long list of command line parameters for the `TacticDisplay`:

- Name of this experiment participant. This must match the entry in the control center's list of participants to contact.
- *X* and *Y* coordinates of the lower left corner of the display area, in "real life" units
- Width and Height of the display area
- *X* and *Y* coordinates of the radar sensor
- Radius of the circular area of radar reception

Again, it might be useful to put these long commands into batch files, to avoid having to type them each time anew.

While waiting for the experiment participants to set up their contact to the RTI and their display components, we can watch how the control center, one by one, discovers the experiment participants' presence and lists them on the "During Simulation..." panel. The whole process might take a couple of seconds, depending on system performance.

After all the negotiations have been completed and all experiment participants reported that they are ready for the simulation run (indicated by the steady green icon on their "During Simulation..." panel entry), the control center now declares the RTI Setup phase for completed, accordingly switches the icons on the "Phases" panel and allows a switching to the next phase.

Before starting the simulation, a more convenient setting for the virtual airplane is entered, starting position: $X = 0$, $Y = 10000$, $Velocity = 500$ and $Heading = 90$ to place it in the middle of the left display boundary, going straight to the right.

Phase 3: Simulation Run

The actual simulation execution is started with `Phases>Run Simulation`. The control center sends out the "Go" signal to all participating applications and starts providing the time steps which serve as master time for all experiment participants. In this case, there is a two second increase in simulation time for every two seconds in real time. Immediately, the experiment participants start counting their own time, which should be fairly synchronous to the master time. The `ContactGenerator` starts displaying and sending the current positions of the airplane. The two `TacticDisplays`

also start their displaying of first and second-hand contacts, usually lagging one time step behind the generation of the respective contacts.

During the 60.0 seconds of the simulation run, we can play around by altering the airplane's course and the `TacticDisplays`' behaviour regarding the treatment of "Reported Contacts".

After the Simulation

After the simulation time has elapsed, all participants stop their simulation actions and wait for further instructions. A red icon with the experiment participants indicates their current stopped status. Now the experiment participant applications can be killed with their remote shutdown buttons from the control center and the RTI shutdown phase can be initiated using the menu `Phases>RTI Shutdown`. After all RTI services have successfully been terminated, we can, as the last step, exit the control center.

5.5 A Few Practical Remarks about the Usage of the CMIF HLA Environment

In the previous section, a sample experiment execution has been discussed. This was to show how the CMIF HLA Environment and the control center are supposed to (and in the described configuration actually do) work together. However, with this very first version of the software, the author cannot guarantee, that it is free of errors, "dead ends" and illogical behaviour. It is likely, that you will encounter bugs or that components will "get stuck" in certain situations. While the work on the

CMIF HLA Environment will be continued –to implement some missing features as well as to eliminate as many of those present problems– right now you should follow the undermentioned rules in case something goes wrong:

- Since otherwise stable behaviour cannot be guaranteed, all participating programs have to be closed, also the control center and the background processes.
- Check if any processes got stuck, under UNIX with `ps -u <username>`, under Windows with the Task-Manager. Look for `rtiexec`, `fedex` and `java`. If necessary, they have to be killed manually, using the `kill -9 <PID>` command. `<PID>`, in that case, is the process ID that was listed by the `ps` command.
- In case of a violent crash, Java writes `core` files. These are quite large and should simply be deleted.

If other errors or bugs become known during the course of the development of a new application that utilizes the CMIF HLA Environment, please contact the author at `Kai.Harth@gmx.de`.

Chapter 6

Conclusion

6.1 Assessment of Results

During the implementation of the CMIF HLA Environment, it became more and more obvious, that the High Level Architecture is a highly sophisticated and professional product. It proved to be well thought out on the conceptual level (HLA) as well as on the technical level of the RTI implementation. With its enormous versatility and flexibility, the problem for a small-scale project like this was rather to grasp what the RTI all can do, than to actually make it work according to one's own intentions. In other words, retardations were due to initial misconceptions of the functioning and not to weaknesses in the HLA concept. In this regard it is helpful, that the RTI is really well documented.

Although the author makes no claim whatsoever to fully understand and utilize all concepts and capabilities of the HLA/RTI, it seems like the implementation of

the CMIF HLA Environment was still reasonably successful. The first version seems to live up to its purposes and provide most of the functionalities that were initially planned. The control center offers a graphically appealing and mostly self-explanatory means for the user to operate a distributed simulation experiment within the CMIF HLA Environment. And the application programming toolkit provides the developer with access to the RTI resources while maintaining the intended simplicity.

The following table gives a final overview over the mapping between HLA and the CMIF HLA Environment. It is summarized, how the various concepts of the High Level Architecture are implemented and substantiated.

High Level Architecture	CMIF HLA Environment
Objects	
any (defined by FOM)	(1... n) CMIFExperimentParticipant, 1 RTIControlModule
Interactions	
any (defined by FOM)	MessageToBus, MessageFromBus, ControlInteraction, StatusMessage
Timing	
Various timing concepts can be implemented (ref. figure 2.2).	Time-scale synchronization with variable scaling factor Sc and variable step increment.
...	...

(High Level Architecture)	(CMIF HLA Environment)
...	...
Timing control is handled flexibly by having federates declare to be <code>timeRegulating</code> and <code>timeConstrained</code> .	"Master-Slave" concept: The control center is <code>timeRegulating</code> and the experiment participants are <code>timeConstrained</code> .
<hr/>	
Communications	
Communications are implemented by having federates issue interactions, all common basic data types are usable.	Experiment participants can communicate by sending <code>MessageToBus</code> and receiving <code>MessageFromBus</code> , while the control center exerts remote control by issuing <code>ControlInteractions</code> . (data type is always <code>String</code>)
<hr/>	
Simulation Behaviour	
Event-Based and/or Time-Stepped	Event-Based and/or Time-Stepped
<hr/>	
Support Tools	
Various support tools are available [Def00a].	The "CMIF Control Center", featuring functionalities for experiment configuration, control and (in a later version) evaluation. The control center is only usable within the CMIF HLA Environment.
<hr/>	
...	...

(High Level Architecture)	(CMIF HLA Environment)
Platforms	
Numerous system platforms and several programming languages.	All platforms, for which a RTI Java binding exists. The programming language is limited to Java.
Summary	
Flexibility and versatility are high.	Flexibility and versatility are reduced, but tailored to CMIF needs.
Complexity is high.	Complexity is extremely reduced.

6.2 Future Work

Although a proof-of-concept has been done for the CMIF HLA Environment, this was only the first step towards a validation of the software. The `DemoApplication` did show, that the CMIF API is in fact usable and that the control center does work –but only on a very undemanding level. Now the software should prove its workableness through the implementation of the first “real” distributed experiment. One that contains actual functionality and is focused on coming up with real results, and not on testing the CMIF HLA Environment functionalities.

Also some work needs to be done on the control center application. Besides the removal of several internal errors, there are still some integral functionalities, that were planned in the initial concept, but could not be implemented yet. Among these are:

- Generation of a log file (communications and additional information) during the simulation run.
- Evaluation (and visualization) of the amount of data being transferred between the experiment participants.
- Advanced control over the inter experiment participant messaging, e. g. emulation of "bandwidth" limitations; advanced routing possibilities.

Only after these steps have been taken will the CMIF HLA Environment be a fully developed and usable software package. Then, hopefully, the CMIF HLA Environment will become the basis for and a part of numerous distributed simulation experiments at CMIF in the future.
